# Privacy-Protected Facial Biometric Verification using Fuzzy Forest Learning

Richard Jiang, Ahmed Bouridane, Danny Crookes, M. Emre Celebi, Hua-Liang Wei

**Abstract** — Although visual surveillance has emerged as an effective technology for public security, privacy has become an issue of great concern in the transmission and distribution of surveillance videos. For example, personal facial images should not be browsed without permission. To cope with this issue, face image scrambling has emerged as a simple solution for privacy-related applications. Consequently, online facial biometric verification needs to be carried out in the scrambled domain thus bringing a new challenge to face classification. In this paper, we investigate face verification issues in the scrambled domain and propose a novel scheme to handle this challenge. In our proposed method, to make feature extraction from scrambled face images robust, a biased random subspace sampling scheme is applied to construct fuzzy decision trees from randomly selected features, and fuzzy forest decision using fuzzy memberships is then obtained from combining all fuzzy tree decisions. In our experiment, we first estimated the optimal parameters for the construction of the random forest, and then applied the optimized model to the benchmark tests using three publically available face datasets. The experimental results validated that our proposed scheme can robustly cope with the challenging tests in the scrambled domain, and achieved an improved accuracy over all tests, making our method a promising candidate for the emerging privacy-related facial biometric applications.

**Index Terms** — Facial biometrics, privacy, face scrambling, chaotic pattern, ensemble learning, fuzzy random forest.

## I. INTRODUCTION

**D**UE to the demands for greater public security over the past decade, video surveillance has become a widely applied technology in the day to day life of public society. As a result, privacy protection [1-7] has become a concern for the public as well as for the legal authorities. Key information such as facial images [1-3, 6, 7] in surveillance videos should not be exposed when distributing videos over public networks. Face scrambling [1-3, 6, 7] has become a promising solution to this issue. By scrambling faces detected in surveillance videos, the privacy of subjects under public surveillance can be respected in modern security technology.

In comparison with encryption, image scrambling has two apparent advantages. First, scrambling usually has much lower computation cost than encryption, making it suitable for computing-efficient network-targeted applications. Second, encryption may undermine the purpose of public security control because its decryption depends on acquiring the encryption key. For example, a security guard who needs to check a key face in a surveillance video may not be able to do so until he/she has the decryption key. In comparison, scrambled faces using the Arnold transform can be easily recovered by manual attempts using the inverse Arnold transform with different parameters.

As a result, face scrambling becomes a compromised choice because it does not really hide information, while unscrambling is usually achievable by simple manual tries even though we do not know all the parameters. It avoids exposing individual biometric faces without really hiding anything from surveillance video. As shown in Refs.[1-7], scrambling has recently become popular in the research field of visual surveillance, where privacy protection is needed as well as public security.

There are many ways to perform face scrambling. For example, scrambling can be done simply by masking or cartooning [8]. However, this kind of scrambling will simply lose the facial information, and hence face recognition becomes unsuccessful in this case. Also for security reasons, it is obviously not a good choice to really erase human faces from surveillance video. In contrast, the Arnold transform [9, 10], as a step in many encryption algorithms, is a kind of recoverable scrambling method. Scrambled faces can be unscrambled by several manual tries. Hence, in this work, we have chosen

Arnold transform based scrambling as our specific test platform.

Automated surveillance systems are installed with online facial biometric verification. While it may not be permitted to unscramble detected faces without authorization due to privacy-protection policies, the ability to carry out facial biometric verification in the scrambled domain becomes desirable for many emerging surveillance systems. Moreover, since unscrambling may involve parameters that are usually unknown by the online software, the need arises to carry out face recognition purely in the scrambled domain.

The task of automatically recognizing various facial images is usually a challenging task. As a result, face recognition has become a prominent research topic in image indexing [6], human-computer interaction [11~15], forensic biometrics [16,

17], medical applications [18], and human cognition [19]. The challenge becomes even more substantial when such facial verification is deployed in visual surveillance systems where videos are usually captured and transmitted on an internet-based visual sensor network. In these situations, face recognition can involve third-party servers where personal privacy needs to be ensured. Further, storage and distribution of recorded surveillance videos are subject to legal constraints especially when human faces are present in videos. As a result, face scrambling will likely be adopted in these visual surveillance systems. The challenge, hence, becomes a question of how to perform face recognition in the scrambled domain without revealing the private contents [1-7]. Consequently, automated facial biometric verification has to be carried out in the scrambled domain. As shown in Fig.1, a scrambled face has a very different appearance from its original facial image. The need for an effective method to handle this new challenge comes along with the new security era.

Commonly in face recognition, dimensionality reduction [20] has usually been considered as the central issue in this challenging task and a number of methods have been introduced in the last decade, including principal component analysis (PCA) [19], independent component analysis (ICA) [21] and Fisher's linear discriminant analysis (FLD) [22]. Combined with kernel methods (KM) [23], these methods can be extended to kernel Hilbert space with a non-linear mapping and we then have their kernel versions such as k-PCA, k-ICA and k-FLD. These approaches can also be applied with 2D/3D face modelling techniques [24~27], combined with various facial features [28, 29], or integrated with support vector machine (SVM) or boosting algorithms. However, it is yet very challenging to construct 3D models automatically from 2D images/views [30]. Besides, for face recognition in the scrambled domain, one needs a robust approach to cope with the chaotic facial patterns typical in surveillance applications.

The random forest method [31, 32] is well suited to handle randomly distributed features, and hence excels at noise-like or chaotic pattern classification. Recent research [33] has also demonstrated that random forests can be effectively applied to the face pose normalization problem. However, in our literature search, the advantage of the random forest method has not been sufficiently exploited for face recognition, and to the best of our knowledge, very few reports on utilizing random forests for image-based face recognition are publically available. An underlying reason is that a facial image cropped from videos usually has a small number of pixels (such as  $32 \times 32$ ), while random subspace sampling requires a larger number of features for sparse sampling.

In this paper, we propose a fuzzy forest learning (FFL) scheme to tackle the scrambled face recognition challenge. In our proposed scheme, a center-surround prior map is applied to guide the random sampling in the scrambled domain, and a fuzzy decision-making mechanism is introduced to weight tree decisions via their fuzzy membership vectors. We then carried out an experimental validation on several scrambled face databases to show the effectiveness of our proposed fuzzy scheme over scrambled facial images.

In the remainder of the paper, Section II introduces the basics

Fig.2. Face scrambling by Arnold transform.

Fig.3. Though it is easy for a human eye to recognize a face from others, it become extremely difficult in the scrambled domain. First row: three faces of two subjects; Second row: their scrambled facial images.

of facial biometric verification in the scrambled domain, section III proposes the construction of a fuzzy random forest, and section IV describes the fuzzy forest decision-making scheme. Section V is a discussion of the parameters in the fuzzy forest learning, and section VI presents experimental results on three face datasets. Conclusions are drawn in Section VII.

## II. FACIAL BIOMETRIC VERIFICATION IN SCRAMBLED DOMAIN

### A. Face Scrambling using Arnold Transform

Digital image scrambling can turn an image into a chaotic and meaningless pattern after transformation. It is a preprocessing step for hiding the information of the digital image, which is also known as information disguise. Image scrambling technology depends on data hiding technology which provides non-password security algorithm for information hiding. The image after scrambling is chaotic, and as a result the visual information is hidden from the public eye and privacy is then protected to a degree even if the visual contents are browsed or distributed over a public network.

Among the various image scrambling methods, the Arnold scrambling algorithm has the properties of simplicity and periodicity. The Arnold transform [9, 10] was proposed by V. I. Arnold in the research of ergodic theory; it was also called cat-mapping before it was applied to digital images. It has been popular in image scrambling because of its simplicity and ease of use. In this paper, we use this scrambling method to set up the test environment of our algorithm in the scrambled face domain.

In the Arnold transform, a pixel at the point  $(x, y)$  is shifted to another point  $(x', y')$  as follows:

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 1 & 2 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \bmod N, \quad (1)$$

which is called two-dimensional Arnold scrambling. The recursive and iterative application of the Arnold transform can be defined as follows:

$$P_{xy}^{k+1} = AP_{xy}^k, \quad P_{xy}^k = (x, y)^T \quad (2)$$

Here, the input is pixel  $(x, y)^T$  after the  $k$ -th Arnold transform,  $P_{xy}^{k+1}$  on the left is the output for the  $k+1$ th Arnold transform.  $k$  represents the number of iterations, where  $k = 0, 1, 2$  and so on.

By replacing the discrete lattice for transplantation, the Arnold transform produces a new image after all of the points of the original image have been traversed. In addition to its simplicity, Arnold scrambling also has the properties of being cyclic and irreversible. This implies the facial information is kept entirely after scrambling, even though it appears as a chaotic pattern.

Unlike encryption, scrambling does not really hide information from access. In fact, for surveillance systems, encryption is not encouraged because any unbreakable hiding of information will undermine the purpose of security surveillance. Hence, scrambling is more welcome than encryption in the public surveillance paradigm, where privacy is concerned. It only prevents unwanted exposure of individual faces.

Fig.2-a) shows a face with its facial components (i.e., eyes, nose and mouth) circled by different colors. Fig.2-b) shows the scrambled face after one iteration of the Arnold transform,

where it can be seen that facial components have been drastically distorted. Fig.2-c) and d) shows the scrambled faces after two and three iterations of the Arnold transform. In comparison with Fig.2-b), the scrambled faces in c) and d) are more difficult to identify by human eyes. In this work, we use three iterations of the Arnold transform to scramble all faces.

### B. Challenges in Scrambled Facial Biometric Verification

Classical face recognition algorithms usually can maximize their performance by exploiting facial components. As shown in Fig.1-a), a face can be easily modeled by a 3D mesh that can help attain better face recognition accuracy. However, after a face is scrambled, it is even barely recognizable by human eyes. Fig.3 shows such a case. Before scrambling, faces are easily recognized by the human eye. After scrambling, faces become extremely hard for the human eye to identify or recognize. It is even impossible to find the eyes and mouth in the scrambled patterns. Visual features are somehow randomly scattered in the result space by the scrambling process. As a result, face recognition has to be a pure data-driven classification issue, without utilizing semantic facial components or applying 2D/3D face models to the scrambled image.

To find an effective method for this randomly scattered distortion, in this paper we introduce a fuzzy random forest learning scheme to cope with this challenge. In our method, a random subspace sampling method is applied to extract a subset of features for each fuzzy decision tree. Such random sampling is expected to overcome the scattered distortion and effectively carry out face recognition on a sparse set of features.

## III. FOREST LEARNING OF SCRAMBLED FACIAL BIOMETRICS

### A. Priori based Biased Subspace Sampling

Subspace sampling in random forest reconstruction aims to improve accuracy by exploiting the power of multiple classifiers. In the random subspace selection, a small number of dimensions from a given feature space is selected in each pass, while each classifier is based on the randomized selection of a lower-dimensional subspace. With respect to a set of selected subspaces, each tree generalizes its classification in the lower dimensional subspace for both the training data and the test data.

If we select  $k$  dimensions out of  $n$ , there are  $K=n!/k!(n-k)!$  such selections that can be made, and with each selection a

decision tree can be constructed. While  $K$  can be a large number, for a practical random forest implementation, only a small number of trees (for example 100) are randomly selected to construct a forest. Unlike many other methods suffering from the curse of dimensionality, the high dimensionality of a feature space provides more choices than are needed in practice. Contrary to the well-known Occam's Razor principle, random forest can take advantage of high dimensionality and it improves the generalization accuracy as it grows in complexity. Hence, a sophisticated strategy to construct a high-dimensional feature space is usually favoured by the random forest method.

In face recognition, human vision usually pays more attention to central features [34] (such as eyes and mouth regions in facial images). As shown in Fig.4-a), one can give central features more weight, given that mostly central features form the basic inference elements for human vision to recognize a face. Naturally, in this paper, we consider a biased randomization strategy toward the central facial features. Considering the maximum multiplication factor as  $\omega_s$ , the repetition of each feature is defined as,

$$\omega_k = 1 + \text{round}(\omega_s \exp(-\sqrt{x^2 + y^2})) \quad (3)$$

Here,  $\omega_s$  is a weighting factor,  $x$  and  $y$  are coordinates normalized to the center of the image, and  $\omega_k$  is a center-surround weighting map, as shown in the left image in Fig.4-a). Fig.4-b) shows the scrambled weight map of the center-surround weight map in Fig.4-a).

Given the scrambled facial feature space  $F$ , and a scrambled priori map  $\omega_k$  shown in Fig.4-b), we can then construct a new

Fig.6 Fuzzy tree structure used in our forest learning.

Fig.7. Fuzzy decisions by each tree in the forest. Each column line stands for the computed fuzzy memberships from a fuzzy tree.

larger feature space by multiplying each feature according to their importance. Then we can have a new set of features (pixels or data dimensions) as,

$$F_{new} = \left\{ \underbrace{f_1, \dots, f_1}_{\omega_1}, \dots, \underbrace{f_k, \dots, f_k}_{\omega_k}, \dots \right\} \quad (4)$$

Then randomization is applied to extract a subset of features from the new feature space  $F_{new}$  for each tree to form the forest.

In the random selection procedure, for each pixel, a higher  $\omega_k$  means higher repetition in  $F_{new}$  and so is more likely to be included in each random tree. Fig.4-c) gives an example of a hit map in the construction of 100 trees, where jet color map is used to visualize the hit map on features  $f_k$ . Fig.5 shows the features randomly selected by 100 trees in the feature space, where each row line stands for a tree, and blue dots denote the selected features from the whole feature space for each tree.

### B. Fuzzy Tree Construction in Random Forest

After the features are selected for each tree, we can then construct a fuzzy decision tree based on the selected subspace. For each tree  $\tau_j$ , we apply a method called local sensitive discriminant analysis (LSDA [35], an extended graph embedding approach similar to LPP [36] and LFDA [37, 38]) to project the selected facial feature space  $F^{(j)}$  into an eigenvector-based subspace. LSDA has been shown to be an effective method for handling face classification [35]. Compared to LPP, LSDA has fewer parameters to tune and hence is easier to use for our purpose.

The decision tree is then constructed in the dimension-reduced eigen subspace. The trees constructed in each selected subspace are fully split using all training data. They are, therefore, perfectly correct on the training set by construction, assuming no intrinsic ambiguities in the samples. There are many kinds of splitting functions for tree construction, such as average mutual information [39], oblique hyperplanes [40], simulated annealing [41], perceptron training [42], or SVM-based hyperplane [31]. Piecewise linear or nearest-neighbor splits can be obtained by various kinds of supervised or unsupervised clustering. There are also many variations of each popular method. Each splitting function defines a model for projecting classification from the training samples on to unclassified points in the space.

In our fuzzy tree construction, we employ a simple piecewise linear split, with a Voronoi tessellation of the feature space. Samples are assigned based on nearest-neighbor matching to chosen anchor points. The anchor points are selected as the training samples that are closest to the class centroids. These trees can have a large number of branches and can be very shallow. The number of leaves is the same as the number of training samples.

Fig.6 illustrates the fuzzy tree constructed for this purpose. In the fuzzy decision of each tree, the membership of a query sample to each node is computed, and subsequently a fuzzy membership is computed with respect to every leaf (namely a training sample), and the final output of a fuzzy tree is a vector of memberships to all leaves, instead of a simple binary decision. Consequently, for a fuzzy tree  $\tau_j$  and an input  $x$ , there is an output as a vector of membership; let the probability that  $x$  belongs to class  $z_k$  ( $z_k = 1, 2, \dots, K_c$ ) be denoted by  $\hat{P}(z_k | \tau_j(x))$ ;

then the overall likelihood will be estimated as:

$$\alpha(z_k | \tau_j, x) = \frac{P(z_k | \tau_j, x)}{\sum_i P(z_i | \tau_j, x)} \quad (5)$$

which is the fraction of class  $c$  points over all points that are assigned to  $\tau_j(x)$  (in the training set), where  $z_k$  denotes the  $k$ -th leaf in the decision tree.

An obvious merit of using this fuzziness is to avoid wrong

a) Computed fuzzy weights of all trees in the forest

decisions being made at the early stage of a single tree, and it gives more space for the optimal forest decision. Fig.7 shows an example of fuzzy tree decision. In the visualized image, each column line stands for the computed fuzzy memberships from a fuzzy tree. In total, 300 trees are displayed in the image. The color stands for the value of the initial estimated fuzzy membership to a class  $z_k$  (corresponding to the vertical coordinate) estimated by a tree  $\tau_j$  (corresponding to the horizontal coordinate).

#### IV. FUZZY FOREST DECISION

##### A. Weights of Fuzzy Tree Decision

The process of building a forest from the features leads to many interesting theoretical questions, such as the number of subspaces needed to achieve a certain accuracy, the number of randomized trees needed to balance between speed and accuracy, and the way to combine all the trees together. Different trees can be constructed if different feature dimensions are selected at each split, while the use of randomization when selecting the dimensions is merely a

---

convenient way to explore the possibilities.

Basically, in the construction of the random forest, an ensemble learning algorithm needs to pay attention to two aspects: (i) how to select proper features/subspaces to generate random trees and (ii) how to guarantee a good combination of tree decisions, which means the decision from each tree needs to be weighted in a rational and effective way.

To combine the decision trees in the random forest for face recognition, we propose a method to weigh a tree via its cross-validation in the forest. Given  $N$  classes and  $K$  trees, the decision from a tree can be repeated  $K/N$  times by random chance. We can then estimate the confidence of a tree from its decision by comparing against other trees in the forest by using Kullback–Leibler divergence [14, 36],

$$w_k = \sum_j D_{KL}(\alpha(z | \tau_i) \| \alpha(z | \tau_j)), \quad (6)$$

where

$$D_{KL}(\alpha_m \| \alpha_n) = \sum_k \alpha_{m,k} \ln \frac{\alpha_{m,k}}{\alpha_{n,k}}, \quad (7)$$

With the above formula, the trees having non-consensus decision will be given a reduced weight from cross-validation via Kullback-Leibler divergence.

##### B. Fuzzy Forest Decision

A motivation to build multiple classifiers originates from the method of cross validation, where random subsets are selected from the training set and a classifier is trained using each subset. Such methods can help avoid the tantalizing problem of over-fitting to some extent by withholding part of the training data. A similar idea has been exploited in bootstrapping [43] and boosting [44]. In boosting, the creation of each subset is dependent on previous classification results, and the final decision combination is based on weighted individual classifiers. Similarly, a random forest consists of a number of trees that need to be combined.

The theory of stochastic discrimination [45] has suggested that classifiers can be constructed by combining many components of weak discriminative power with generalization. Classification accuracies are then related to the statistical properties of the combination function. The capability to build classifiers of arbitrary complexity while increasing generalization accuracy is shared by all this type of methods, and decision forest is one such method.

While the forest is based on random selection of subspaces, it is difficult to determine those trees having better accuracies than others, due to the nature of randomness. In our combination procedure, we use the weighting function in Eq.(6), and the fuzzy decision from each tree is then weighted as:

$$\tilde{P}(z_k | \tau_j, x) = w_k \alpha(z_k | \tau_j, x). \quad (8)$$

The final discriminant function is defined as:

$$\phi(z_k | x) = \frac{1}{K} \sum_k \tilde{P}(z_k | \tau_j(x)), \quad (9)$$

and the decision rule is to assign  $x$  to class  $c$  for which  $\phi$  is the maximum:

$$z(x) = \arg \max_{z_k} \phi(z_k | x) \quad (10).$$

For a random forest, the forest decision is usually based on a

plurality vote among the classes decided by each tree. In our scheme, the vote from each tree is fuzzy, and the forest decision is based the combination of weighted memberships estimated from each tree, where odd decisions are neutralized in the fuzzy forest decision process.

Fig.7 shows an example of the initial estimated fuzzy membership vectors of 100 trees. Here, the membership is visualized by ‘jet’ colormap. Fig.8-a) gives the weighting scores of all 25 trees computed from Eq.(6) using Kullback–Leibler divergence among their membership vectors. Fig.8-b) shows a case where a direct average made a wrong decision and the proposed fuzzy combination corrected it. Here the test (see Section V) is based on the Yale face dataset. By using the proposed fuzzy combination, the likelihood of the wrong choice at the 13<sup>th</sup> leaf in the trees is decreased (shown as a red downward arrow) and the correct choice at the 78<sup>th</sup> leaf is increased (shown as a red upward arrow). As a result, the wrong decision is corrected from the 13<sup>th</sup> label to the 78<sup>th</sup> label, thanks to the proposed fuzzy combination.

### C. Overview

Fig.9 gives an overview of the proposed fuzzy forest learning scheme for the scrambled facial verification. Given a training dataset, faces are scrambled and forwarded to the fuzzy forest learning scheme. The procedure then randomly selects the features from the scrambled domain with biased weights toward central features, and a number of fuzzy trees are constructed based on the selected features, where LSDA is applied to further extract discriminant features from randomly selected features.

After a scrambled face is input as a test, each tree computes a fuzzy vector of membership and forwards it to the forest decision process. The forest decision procedure then weighs each tree via their total Kullback-Lieder divergences from all other trees, while the final decision is based on a fuzzy combination of all trees. List I gives the pseudocode of the proposed method.

## V. PARAMETERS IN FUZZY FOREST LEARNING

Before we go further for experimental validation of our proposed method, we need to answer several critical questions. How many trees are we are going to use? How many features should we select for a tree? What is the best value for the biased factor  $\omega_s$  in Eq.(3)? Does the fuzzy decision via KL divergence really work better than direct averaging? These questions could be pursued to lead to deeper theoretical analysis. In this paper, however, we instead treat these questions in a practical way, and try to optimize these parameters using several experiments.

In our experiment, we ran our tests on the Yale dataset [22]. The Yale dataset has 15 subjects and each subject has six sample faces. With this small dataset, we carried out the face verification experiments by splitting the small dataset into training and test datasets, where the training dataset has five facial images per subject. We then varied the parameters and ran experiments to see which parameter values gave the lowest error rates. Fig.10 shows our experimental results.

In Fig.10-a), the bias factor  $\omega_s$  is varied from 0 (no bias) to 5.5. Here, 100 trees are constructed and the sampling ratio is set to 5%. It can be clearly seen that by increasing the bias factor,

a) Effect of varying the biased sampling factor  $\omega_s$

b) Effect of varying the sampling ratio in FFL

c) Results for different numbers of trees in FFL

Fig.10 Learning parameters in our proposed FFL scheme.

the error rate is reduced from 12.0% to 8.8% around  $\omega_s=3.25$ . Obviously from the test, it is shown that the biased sampling did improve the classification accuracy.

In Fig.10-b), the sample ratio is varied from 0.5% to 10.5%, and it can be seen that the error rate decreases to 8.0% when the sample ratio is tuned from 0.5% to 3.25%, and it then rises back slowly towards the baseline (12%, the error rate for the original LSDA method) when the sample ratio is increased. Here, 100 trees are generated to form the forest and  $\omega_s$  is set to 3.25. From this experiment, we can also see that the random forest does not necessarily work better than a single tree based method if its parameters are not selected properly.

Fig.10-c) gives the experiment on varying the number of trees.

a) Subjects in the ORL database

b) Subjects in the PIE database

c) Subjects in the CK+ dataset

Fig.11. Three face databases used in our benchmark test.

Setting the sample ratio to 3.25% and  $\omega_s$  to 3.25, the number of trees was varied from 3 to 145. We can see that the error rate tends to decrease when the number of trees is increased, and its fluctuation becomes smaller as well. When the number of trees is increased to 80, the error rate is further reduced to 7.7%. Basically, more trees mean more computing time. Provided we have a stable lowest error rate, using fewer trees is usually a favorite choice.

Fig.10-c) also shows a comparison between direct average (the blue curve) and fuzzy combination (the red curve). It can be seen that fuzzy combination can attain better accuracy consistently in the tests. Fig.8-b illustrates how this can be achieved by showing one case in the test of Fig.10-c). Using the proper fuzzy combination, the likelihood is reduced with respect to the wrong choice (the 13<sup>th</sup> leaf) and increased with respect to the correct choice (the 78<sup>th</sup> leaf). Consequently, a correct decision is attained by the fuzzy combination.

64.8	64.9	73.2	74.3	78.5	67.7	85.1	85.6

b) Over all accuracy of all  $k$  tests

Fig.13. Test results on the PIE dataset.

have carried out systematic experiments on three databases: ORL database [46], PIE database [47] and PUBFIG wild face database [48]. Fig.11 shows typical faces in these databases and their scrambled images. The ORL database has 40 subjects with 10 faces each at different poses. The CMU PIE database has 41,368 faces, comprising 68 classes with about 170 faces per class (we use 100 faces per subject, similar to Ref.[36]). PUBFIG database [48] contains wild faces selected from internet. It is very similar to LFW database [49] but it provides standard cropped faces. As has been shown [49], background textures in LFW can help achieve a higher accuracy. While we consider facial region recognition only, PUBFIG fits better with our purpose.

In our experiment, all code was implemented in Matlab, and ran on a PC with 2.7GHz dual-core Intel CPU. In our experiment, we have used a test scheme called *leave-k-out*[50]. If each subject has  $N$  faces in a dataset, we leave  $k$  faces out of the training dataset for testing. As a result, the benchmark test will have  $(N-k)$  training faces per subject. Selecting  $k$  samples from  $N$  faces will have  $C_N^k$  choices. To make it feasible, we just chose consecutive  $k$  faces from  $N$  samples and then we have  $N$  tests in turn for a *leave-k-out* experiment. The accuracy is the average of all  $N$  tests. It is noted that the consecutive splitting

Fig. 14. Test results on PUBFIG wild faces.

will usually have a large difference between test and train datasets, because faces in datasets usually change consecutively and the first  $k$  faces are usually very different from the last  $(N-k)$  faces.

Our benchmark tests aim to verify whether or not our proposed fuzzy random forest learning scheme can enhance the accuracy of face recognition. In our approach, we have proposed a computing-efficient data-driven facial biometric classification method. Hence, we compare our approach with a number of typical data-driven methods, including PCA[21], LDA[22], kPCA[23], kLDA[23], LPP[36], and LSDA [35].

Because random forest is based on random feature selection, it may give a different accuracy each time. As a result, we ran each test ten times and recorded the average (FFL-Mean) and maximum (FFL-Best) accuracies for comparison. It is also noted that for each test there were  $N$  sub tests due to the different selection of the *leave-k-out* scheme. So in total we have  $10 \times N$  subtests for each *leave-k-out* test.

#### B. Validation on ORL dataset

The ORL database has 10 faces per subject. In our *leave-k-out* test,  $k$  varies from 2 to 6. In total we have 5  $k$ -tests, where each  $k$ -test has  $10 \times 10$  subtests. The final accuracy is the average on all 100 subtests.

Fig. 12-a) shows all *leave-k-out* tests, where  $k$  varied from 2 to 6. We can see that our proposed FFL method attained the best accuracy in all  $k$  tests. It is also observed that FFL-mean is very

close to FFL-best. In our test, each forest has nearly 80 trees, and such a large number of trees can effectively quench the stochastic fluctuation in the random feature selection. Besides, each  $k$ -test has  $10 \times 10$  subtests, making it statistically similar.

Fig. 12-b) lists the overall accuracy by averaging all  $k$  tests. Here, we included PCA, LDA, kPCA, kLDA, LPP and LSDA for comparison because they are typical data-driven face recognition technology. We can see that our FFL attained the best accuracy over all  $k$ -tests – around 98%, while LPP came second to this at 96.8%. kLDA and LDA attained similar accuracy around 96.2%, LSDA attained 94.1%, and kPCA and PCA had an accuracy of 90.7%.

#### C. Validation on PIE dataset

In this benchmark test, 100 faces per subject and in total 6700 faces from the PIE dataset were used. In the test scheme,  $k$  faces from 100 samples per subject are selected as test samples, and the rest are used as training samples. In our experiment, we repeatedly selected  $k$  faces (consecutively) from 100 samples ten times, and carried out 10 subtests per  $k$  test. Random forest can vary from time to time due to its random mechanism. As before, for each subtest, we ran 10 times and used both average and best accuracy to evaluate our FFL classifier.

Fig. 13-a) shows all *leave-k-out* tests on the PIE dataset, where  $k$  varied from 10 to 50. We can see that our proposed FFL method attained the best accuracy in all  $k$  tests. It is also observed that FFL-mean is very close to FFL-best. It is also noticed that when  $k$  rises to 50, LSDA, LDA and kLDA have the largest drop in accuracy. In comparison, the proposed FFL method attained steady performance even when the number of available training samples is reduced.

Fig. 13-b) lists the overall accuracy by averaging all  $k$  tests. We can see that PCA and kPCA have the lowest accuracy of around 65%, LSDA has an accuracy around 67.7%, LDA and kLDA attained similar accuracy around 74%, and LPP attained an accuracy at 78.5%. In comparison, our FFL method attains a far better accuracy of around 85% in this test.

#### D. Validation on PUBFIG dataset

The PUBFIG dataset has been developed for benchmark tests to compare various algorithms against the human vision system. Its typical benchmark test can have as many as 20,000 pairs of faces for comparison. However, in the surveillance-targeted scrambled domain, human perception can barely recognize any scrambled faces, making it meaningless to carry out this human-targeted comparison test. On the other hand, in surveillance applications, users (such as police) usually have a set of wanted faces in their training datasets on the server side, making it more like a *leave-k-out* experiment. For this reason, we need to design a suitable evaluation scheme for this work.

In our experiments, we have selected 52 subjects with 60 faces each, and split them randomly into test and training datasets, with each having  $30 \times 52 = 1560$  faces. We have then test all data-driven methods by comparing each test face against all training faces. In total, we have  $1560 \times 1560 = 2.4$  million pairs of estimated likelihood values which forms a likelihood matrix of  $1560 \times 1560$  elements. Then we have

varied the thresholds on the likelihood matrix, and counted how many pairs below the threshold are false positive and/or true positive. False positive rates and true positive rates can then be computed accordingly, and we can have the ROC curves (FP versus TP) as our evaluation criteria.

Fig.14-a) gives our test results on all methods. It is observed that PCA has given worse performance than it did on LFW [49]. This implies that this test is even harder than the standard LFW test in [48] (at least it is true for Eigenfaces). From the comparison results, we can clearly see that the proposed FFL method appears to have better performance in this test on real-world faces, with significantly better true positive rates (TPR) consistently over other data-driven methods. Fig.14-b) gives the true positive rates at FPR=20%. PCA and kPCA attain a low accuracy of around only 30%, while FFL attains an accuracy of around 76.6%, about 20% higher than LSDA, LPP, LDA and kLDA.

## VII. CONCLUSIONS

In this paper, we have successfully developed a robust fuzzy forest learning scheme for facial biometric verification in the scrambled domain. In our proposed scheme, to extract the features from scrambled face images robust, a biased random subspace sampling scheme is applied to construct fuzzy decision trees from randomly selected features. Then a fuzzy forest decision is obtained from all fuzzy trees by the weighted combination of their fuzzy decision vectors of membership. Our experiments using three public datasets have successfully validated that the proposed fuzzy forest learning scheme can robustly cope with challenging tests in the scrambled domain, and it consistently attained the best accuracy over all datasets, making our method a promising candidate for emerging privacy-related facial biometric applications, especially for public visual surveillance systems where face scrambling is applied.

It is worth highlighting that our approach is not dependent on any semantic face models or 3D templates. Though face specific features targeted towards semantic/3D face modelling can enhance accuracy, face modelling from images and facial component detection needs extra computation time and can also easily introduce extra errors. Instead, our approach is based purely on data-driven classification, and can easily be applied to other similar chaotic pattern classification cases, such as texture classification in image analysis or factor analysis of stock prices. In our future work, we plan to investigate the use of our method in these applications.

**Richard Jiang** is currently a Lecturer in the department of Computer Science and Digital Technologies, Northumbria University, Newcastle upon Tyne, United Kingdom. He received his PhD in Computer Science from Queen’s University Belfast, Belfast, UK, in July 2008.

After his PhD study, he has been working in Brunel Univ., Loughborough Univ., Swansea Univ., Univ. of Bath and Univ. of Sheffield. He joined Northumbria in May 2013. His research interests mainly reside in the fields of Artificial Intelligence, Man-Machine Interaction, Visual Forensics, and Biomedical Image Analysis. His research has been funded by EPSRC, BBSRC, TSB, EU FP, and industry funds, and he has authored and coauthored more than 40 publications.

**Ahmed Bouridane** (M’98–SM’06) received the “Ingenieur d’État” degree in electronics from Ecole Nationale Polytechnique of Algiers (ENPA), Algeria, in 1982, the M.Phil. degree in electrical engineering (VLSI design for signal processing) from the University of Newcastle-Upon-Tyne, U.K., in 1988, and the Ph.D. degree in electrical engineering (computer vision) from the University of Nottingham, U.K., in 1992.

From 1992 to 1994, he worked as a Research Developer in telesurveillance and access control applications. In 1994, he joined Queen’s University Belfast, Belfast, U.K., initially as Lecturer in computer architecture and image processing and then as a Reader in computer science. He became a Professor in Image Engineering and Security at Northumbria University at Newcastle (U.K.) in 2009. His research interests are in imaging for forensics and security, biometrics, homeland security, image/video watermarking and cryptography. He has authored and co-authored more than 200 publications.

**Danny Crookes** was appointed to the Chair of Computer Engineering in 1993 at Queens University Belfast, and was Head of Computer Science from 1993 to 2002. He is Director of Research for Speech, Image and Vision Systems at the Institute for Electronics, Communications and Information Technology (ECIT) at Queens University Belfast.

His current research interests include the use of novel architectures (especially GPUs) for high-performance image processing. He has applied expertise in language design, optimizing compilers and software generators, plus software tools for

hardware description and architecture generation, to the goal of developing high level software tools to enable rapid development of real-time video processing systems. He is currently involved in projects in automatic shoeprint recognition (ESPRC), speech separation and enhancement (EPSRC) and processing of 4D confocal microscopy imagery (sponsored by INI and Andor Technologies). He has published over 200 scientific papers in journals and international conferences, and has presented tutorials on parallel image processing at several international conferences.

**M. Emre Celebi** (S'05–M'07–SM'11) received the B.Sc. degree in computer engineering from the Middle East Technical University, Ankara, Turkey, in 2002 and the M.Sc. and Ph.D. degrees in computer science and engineering from The University of Texas at Arlington, Arlington, TX, USA, in 2003 and 2006, respectively.

He is currently an Associate Professor with the Department of Computer Science, Louisiana State University in Shreveport, Shreveport, LA, USA. He has pursued research in the field of image processing and analysis. He has published more than 120 articles in journals and conference proceedings. His recent research is funded by grants from the National Science Foundation.

**Hua-Liang Wei** received the B.Sc. degree in mathematics from Liaocheng University, Shangdong Province, China, in 1989, the M.Sc. degree in automatic control theory and applications from Beijing Institute of Technology, Beijing, China, in 1992, and the Ph.D. degree in signal processing and control engineering from the University of Sheffield, Sheffield, U.K., in 2004.

He previously held academic appointments (Lecturer and Associate Professorship) from 1992 to 2000 at Beijing Institute of Technology, Beijing, China. He joined the Department of Automatic Control and Systems Engineering, the University of Sheffield in 2004, where he is currently a Lecturer. His current research interests include modeling and identification methods for nonlinear systems; NARMAX methodology and its applications; signal and image processing; pattern recognition; spatiotemporal systems; neuroimaging, data modeling and analysis; wavelets and neural networks; applications of signal processing, system identification, and modeling in complex system analysis including systems/synthetic biology and biomedical engineering; forecasting of stochastic and dynamical processes; regression analysis; and linear and nonlinear optimization.
